CHEMICAL COMPOSITION OF SORGHUM FORAGE AT VARIOUS STAGES OF VEGETATIVE GROWTH JAMES E. WEBSTER, JOHN B. SIEGLINGER,2 and FRANK DAVIES2

Oklahoma Agricultural Experiment Station, Stillwater

INTRODUCTION

Sorghums are one of the major crops grown in Oklahoma and they are used to produce both forage and grain. Cooperative experiments have been directed toward securing a comprehensive knowledge of the chemical composition of the plant at all stages of growth. In collecting samples for detailed carbohydrate and nitrogen analyses, samples of the whole plant at various stages of growth up until heading time became available. Considerable published data regarding the composition of mature sorghum forage (Morrison, 1936) intended for feeding purposes is already available and can be used in connection with these figures. Since very little is known about the feeding value of immature plants and inquiries on this point are occasionally received, it was decided to use the available samples to determine the feeding value as shown by the conventional proximate analysis for feeding stuffs.

METHODS

Sampling. The plants used for these analyses were grown on bottom land, and were planted and cultivated according to the best practices recommended for such crops. Samples were secured by cutting the desired number of plants in the field and immediately bringing the samples into the laboratory where they were ground in a power meat grinder. Portions were taken from the well-mixed material and dried on a steam hotplate at about 80° C. Later the samples were oven-dried at 105° C and finely ground in a Wiley cutting mill before being stored in sealed glass jars. The number of plants used varied with the size of the stalk and ranged from several hundred when small to a minimum of twelve to fifteen at later sampling periods.

Moisture. Samples were removed from the freshly ground material and dried to constant weight at 105° C.

Proximate analyses. These analyses were performed according to the directions given by the A.O.A.C. (Anon. 1940) under the section headed Grain and Stock Feed Analyses.

RESULTS

Data are given in the tables for samples from two years. The stage of maturity is indicated by the age of plants given as days from planting and by the height of stalks (average height of the cut plants in the laboratory). At any one sampling there was a considerable range in height and quoted figures are to be considered accordingly. The varieties used are two strains of dwarf kafir, No. 60-21, a chinch-bug-resistant strain, and 58-19, a susceptible strain; and two durras, Pig Nose, C. I. No. 696, 2 chinch-bug-susceptible variety and Corneous C. I. No. 695, a resistant variety. In studying these figures one of the most interesting columns is that for water, where the value remains relatively constant during the period This means that any appreciable change in the proximate ancovered. alyzes is chiefly due to changes during growth and is not due simply to an increase in dry matter, as is usually the case after heading. Ash values show the greatest changes and here we have to consider the fact that the small plants have a relatively large amount of soil on them which was not

ACADEMY OF SCIENCE FOR 1945

removed in the process of harvesting. The recorded figures are certainly too high for true ash but they are what would be found if the plants were harvested at this stage of growth. Another interesting value is the ether extract, where the results for the two years are quite dissimilar. No explanation is known for this difference unless it is due to seasonal differences, which were extreme. As indicated previously there is little published information regarding the composition of immature sorghum forage. Detailed carbohydrate, ash, and protein figures are given for the composition of Atlas and Milo at various stages of growth up until heading, in the bulletin by Webster and Heller (1942). The results in this bulletin, however, are not in a form that can readily be transferred into the usual feeding units.

Probably the most significant figure in the tables is that of protein because this value is relatively high. Examination of the values expressed on a dry-weight basis shows that protein comprises at least one-sixth and often a fifth of the total dry weight. These figures would indicate that the dried immature sorghum forage is higher in protein than average for good alfalfa hay and much higher than most of the hay crops ordinarily harvested in this country. The crude fiber is correspondingly low and the nitrogen-free extract is relatively high. These results point to the desirability of further chemical studies on the composition of immature sorghum forage.
